9 In the course of developing this model, we found that we were unable to reproduce the expected
10 correlation between change in bond length and change in harmonic frequency for O–H stretches.¹
11 We ultimately determined that the failure of our model to reproduce this correlation was due to
12 a lack of coupling between our bonding potential and the environment. To that end, we extended
13 our morse potential to be field-dependent in a manner first described elsewhere.¹ In short, the
14 field-dependence of the potential requires specifying the first and second dipole derivatives along
15 the O–H stretch.

16 Rather than treating these as fitting parameters, we computed the dipole derivatives from
17 electronic structure as follows. First, we scan along an O–H stretch and compute the total dipole
18 moment, μ , at each point along the scan. This dipole moment is then projected onto the O–H
19 bond vector, $\mu_{\text{OH}} = \frac{R_{\text{OH}} \cdot \mu}{|R_{\text{OH}}|}$. This allows us to isolate how the dipole changes as the O–H vibrates
20 in a particular environment.

21 We considered three different environments to see how the dipole derivatives depend on the
22 local environment and ultimately chose a set of parameters we deemed appropriate for polarization
23 and one to represent the full system. Remember that in EDA, the polarization energy represents
24 the response of a molecule to the rest of the environment plus mutual polarization. To that end,
25 we computed an O–H stretch of an isolated H₂O in a polarizable continuum described by the
26 COSMO model.² This resulted in the dipole surface shown with circles in Fig. 1. The lines are fits
27 with a second order polynomial, $\Delta\mu_{\text{OH}} = \mu_{\text{OH}}^{(1)}\Delta R_{\text{OH}} + \mu_{\text{OH}}^{(2)}\Delta R_{\text{OH}}^2$. For H₂O in a dielectric, we find
28 $\mu_{\text{OH}}^{(1)} = 0.345$ and $\mu_{\text{OH}}^{(2)} = 0.095$. This is to be compared to the same values for an isolated H₂O of
29 $\mu_{\text{OH}}^{(1)} = 0.165$ $\mu_{\text{OH}}^{(2)} = -0.012$. The effect of an environment is, therefore, to promote dissociation to
30 ionic products rather than radicals which is what the change in sign of $\mu_{\text{OH}}^{(2)}$ implies and to make
31 it easier to elongate the O–H bond which is what the magnitude of $\mu_{\text{OH}}^{(1)}$ means.

32 Interestingly, when the environment is represented by an actual molecule, as with (H₂O)₂,
33 the second dipole derivative increases by a lot and increases even further when when a dielectric
34 continuum is used. This is seen in the points marked with squares in Fig. 1. We attribute this
35 large non-linearity in the dipole surface to the role of charge delocalization, which makes these
36 parameters suitable for the full potential which includes charge transfer.

37 A water dimer, however, is not a representative environment for liquid water, or even large water
38 clusters. To remedy this, we constructed a tetrahedrally coordinated water dimer, (H₂O)₂₊₆. The
39 notation (H₂O)₂₊₆ indicates that this is a water dimer solvated by six other water molecules. The
40 cartesian coordinates are available with the manuscript. When this larger solvation environment
41 is used, we see a further increase in the dipole derivatives beyond just a water dimer. The dipole
42 derivatives for the central O–H stretch in (H₂O)₂₊₆ are $\mu_{\text{OH}}^{(1)} = 1.082$ and $\mu_{\text{OH}}^{(2)} = 1.54$. When these
43 values are used in the model, the $\Delta\omega$ vs ΔR_e slope is $\approx -17.1 \text{ cm}^{-1}/.001$ over the same clusters.

Supplementary Figure 1: *Projected dipole moments along various O-H stretches.* The dipole moment of (H_2O) , $(\text{H}_2\text{O})_2$, and $(\text{H}_2\text{O})_{2+6}$ are computed with $\omega\text{B97X-V/def2-QZVPPD}$ as a function of the O–H stretch distance. All other degrees of freedom are fixed. The dipole moment is projected along the O–H stretch unit vector. $(\text{H}_2\text{O})_{2+6}$ is a water dimer with six additional water molecules placed so that the water dimer is tetrahedrally coordinated. The blue points and lines are gas-phase systems while the red points and lines include a polarizable continuum. Each point is connected vertically to make it clear they are the same structure but in the presence of a polarizable continuum. Circles are used for a single water molecule, squares for a water dimer, and triangles for the tetrahedrally solvated water dimer. See text for more details and values of computed dipole derivatives.

44 In principle, the curves in Figure 1 should eventually be equal when sufficient explicit solvent
 45 is included in the calculation. Since the dipole derivatives computed from $(\text{H}_2\text{O})_{2+6}$ are not suffi-
 46 cient to reproduce the Badger correlation, we increase the dipole derivatives until the appropriate
 47 correlation is reproduced. This results in values of $\mu_{\text{OH}}^{(1)} = 1.19$ and $\mu_{\text{OH}}^{(2)} = 3.69$. To be completely
 48 rigorous, these dipole derivatives should be functions of the local environment, but we have not
 49 explored that possibility in this work since choosing them to be constants works quite well.
